1                   **Effects of Parking Provision on Automobile Use in Cities: Inferring Causality**  
2

3                   **ABSTRACT**

4                   Many cities include minimum parking requirements in their zoning codes and provide ample  
5                   parking for public use. However, parking is costly to provide and encourages automobile use,  
6                   according to many site-specific studies. At the city scale, higher automobile use is linked to  
7                   traffic congestion, environmental degradation and negative health and safety impacts, but there is  
8                   a lack of compelling, consolidated evidence that large-scale parking increases cause automobile  
9                   use to rise.

10                  In this study, we apply the Bradford Hill criteria, adopted from the field of epidemiology,  
11                  to determine whether increases in parking should be considered a likely cause of citywide  
12                  increases in automobile use. We rely on prior research and original data from nine U.S. cities  
13                  dating back to 1960. We find that an increase in parking provision from 0.1 to 0.5 parking spaces  
14                  per person is associated with an increase in automobile mode share of roughly 30 percentage  
15                  points. We also demonstrate that a majority of the Bradford Hill criteria can be satisfied using  
16                  the available data, which offers compelling evidence that parking provision is a cause of  
17                  citywide automobile use. Given the costs associated with parking and its apparent effects on  
18                  automobile use, our findings warrant policies to restrict and reduce parking capacity in cities.

## Effects of Parking Provision on Automobile Use in Cities: Inferring Causality

### INTRODUCTION

Most municipalities in the U.S. set minimum parking requirements (1). These policies assume that the appropriate supply of parking can be determined by estimating the potential demand and aiming to meet that demand. This view is reinforced through the Institute of Transportation Engineer's *Parking Generation* (2) and similar guides. However, it typically fails to account for the complex relationships between parking supply and demand. This is problematic for many well-documented reasons. Parking is expensive to provide, thereby driving up construction and rental prices; it consumes large amounts of space, thereby limiting development potential; and it often encourages driving (3).

This last point—the influence of parking on automobile use—is the primary focus of this study. There is a substantial body of literature describing the many ways that the price and availability of parking influence automobile use and travel behavior. For example, the price of parking at work influences whether employees choose to drive alone (4–6). It also influences where and when people choose to travel for discretionary trips and where they choose to park once they arrive (7). Guaranteed parking at home influence whether commuters drive to work, versus taking transit (8, 9).

These studies suggest that minimum parking requirements, public parking provision, and other mechanisms that push citywide parking supplies upward could potentially cause citywide automobile use to increase over time. Prior research has shown that parking supply and automobile use are correlated across different cities (10, 11) and that automobile use increased considerably in cities where parking increased (12, 13).

The primary question in this study, therefore, is one of causality: do citywide changes in parking actually cause automobile use to increase, or are minimum parking requirements an appropriate response to already rising automobile use? The purpose of this study is to consolidate the available knowledge, contribute original data, and apply a robust, scientifically accepted framework for inferring whether causality exists. In addition to prior research, we rely on data related to parking provision and automobile use for nine U.S. cities in the years 1960, 1980 and 2000, which let us track and analyze changes over time.

Causality has been the subject of numerous prior travel behavior studies—particularly those aiming to parse out the effects of residential self-selection. The most common approaches, in lieu of controlled experimental design, include direct questioning through surveys, statistical models that control for residential location choices, and longitudinal studies, or some combination of each (14–16).

Several studies use household travel surveys to control for residential location, which the authors consider a treatment effect that explains attitudinal differences (17–19). Several other studies rely on a comprehensive travel survey administered across eight neighborhoods in northern California in 2003, which includes information about attitudinal differences, how recently a resident moved and their current location—allowing the authors to conduct cross-sectional and quasi-longitudinal analyses (14, 15, 20). Similarly, Joh et al. (21) rely on the South Bay Travel Survey administered between 2005 and 2007, controlling for attitudes about walking.

Since we are interested in understanding changes in parking supply and travel behavior at the city scale over multiple decades, our options for parsing out causality are especially limited. Comprehensive travel surveys and detailed location data are not available. The most consistent source of travel data are from journey to work surveys administered by the U.S. Census Bureau

1 each decade dating back to 1960. Since no reliable database of historical parking supply exists,  
2 we are left to develop our own estimates using available aerial photographs. The effort required  
3 to develop these estimates limits our potential sample size considerably. These limitations rule  
4 out many common approaches including controlled experiments, direct questioning, and  
5 statistical modeling.

6 Instead, we rely on a widely-accepted general theory of causality, adopted from the field  
7 of epidemiology, commonly referred to as the Bradford Hill criteria (22–25). The nine criteria,  
8 first presented in a 1965 speech by Sir Austin Bradford Hill, a Professor Emeritus at the  
9 University of London, are intended for inferring causality when an association already exists.  
10 They are not meant to serve as a checklist or set of rules, but instead to answer the question: what  
11 aspects of an association should we especially consider before deciding that the most likely  
12 interpretation is causality? (22) According to Hill, “the decisive question is whether the  
13 frequency of the undesirable event B will be influenced by a change in the environmental feature  
14 A” (22).

15 In our case, an environmental feature A refers to parking supply and the event B refers to  
16 high levels of automobile use, which many policymakers consider undesirable due to a range of  
17 environmental, social, and economic consequences, including traffic congestion, traffic deaths,  
18 and pollution. This approach lets us overcome an inherent challenge, which is that there are  
19 many potential explanatory variables (e.g., changes in transit service quality) and a lack of  
20 reliable data for many of those variables. By approaching the question of parking supply and  
21 automobile use in this way, we cannot discredit other factors, but we can gain a reasonably  
22 definitive answer regarding the potential citywide impacts of parking on travel behavior and  
23 make evidence-based policy recommendations to achieve long-term transportation-related goals.

24 By demonstrating that parking contributes to rising automobile use, this research calls  
25 into question the underlying justification for minimum parking requirements in urban areas.  
26 These requirements, like many transportation policies, employ a predict-and-provide approach  
27 through which planners and designers provide infrastructure based on estimates of future  
28 demand. If our hypothesis that parking causes driving is true, however, then parking has an  
29 induced demand effect (26), which should be taken into account and managed accordingly  
30 through mechanisms like maximum parking allowances and pricing.

## 31 **DATA AND METHODOLOGY**

32 For this study, we walk through the Bradford Hill criteria, using them to gain a better  
33 understanding of whether parking provision is a likely cause of automobile use in American  
34 cities. We rely on original data and analysis, as well as additional knowledge gained from prior  
35 studies.

36 Our study begins in 1960 when the earliest, most consistent data are available. We  
37 consider three specific points in time—1960, 1980 and 2000—and the two time periods those  
38 dates represent (before and after 1980).

### 39 **City selection**

40 Some historical data used in this study are only available at the city scale, which prevents us  
41 from conducting more fine-grained analyses of individual neighborhoods. Therefore, we only  
42 include cities that are reasonably similar in size and form. We selected nine medium-sized U.S.  
43 cities—building upon earlier studies (10, 12, 13)—from a database of more than 100 cities based  
44 primarily on population size and changes in automobile use between 1960 and 2000. Their  
45  
46

1 population size ranges from approximately 100,000 to 300,000 people and none of the cities  
2 experienced marked population growth over the study period, indicating they were largely built  
3 up by 1960. The cities represent a full range in automobile use, including some with  
4 exceptionally low automobile mode shares. Connecticut and Massachusetts are heavily  
5 represented due to the availability of historical aerial photographs from university libraries in  
6 each state.

### 8 **Parking supply data**

9 The main source of original data for this study—and an important contribution of this work—  
10 pertains to parking provision as early as the 1950s and as recently as 2009. To our knowledge,  
11 this is the most comprehensive set of historical, citywide parking supply data that exists.

12 To estimate available parking supplies, we first compiled high-resolution aerial  
13 photographs for the following years:

- 14 • Albany, New York: 1952, 1994 and 2007
- 15 • Arlington, Virginia: 1957, 1985 and 2009
- 16 • Berkeley, California: 1958, 1985 and 2009
- 17 • Cambridge, Massachusetts: 1952, 1985 and 2009
- 18 • Hartford, Connecticut: 1957, 1985 and 2009
- 19 • Lowell, Massachusetts: 1952, 1985 and 2005
- 20 • New Haven, Connecticut: 1951, 1985 and 2008
- 21 • Silver Spring, Maryland: 1964, 1988 and 2009
- 22 • Somerville, Massachusetts: 1955, 1978 and 2008

23  
24 Some researchers have estimated parking supplies by evaluating individual sites using  
25 field data (28, 29) or online tools like Google Streets and Bing Maps (30). Unfortunately, these  
26 methods aren't available for estimating historical parking supplies, nor would they let us achieve  
27 the desired scale of analysis within our resource constraints.

28 We identified land used for off-street parking in geographic information systems (GIS)  
29 by visual inspection using methods outlined by McCahill and Garrick (13) and similar to those  
30 described by Davis et al. (27). This includes any visible off-street parking facility with more than  
31 three spaces, including multi-level parking structures. For older aerial photographs, which are  
32 generally of lower quality, we determined a minimum and a maximum area of parking for each  
33 city and report the midpoint of that range.

34 To estimate the total number of parking spaces, we divided the total area by 350 square  
35 feet (32.5 square meters)—the average area per parking space, based on a sample of 100 lots. We  
36 multiplied the footprint of parking structures by four to estimate their rough capacity. Values for  
37 1960, 1980 and 2000 were estimated from values in known years using linear interpolation or  
38 projection.

### 40 **Census data**

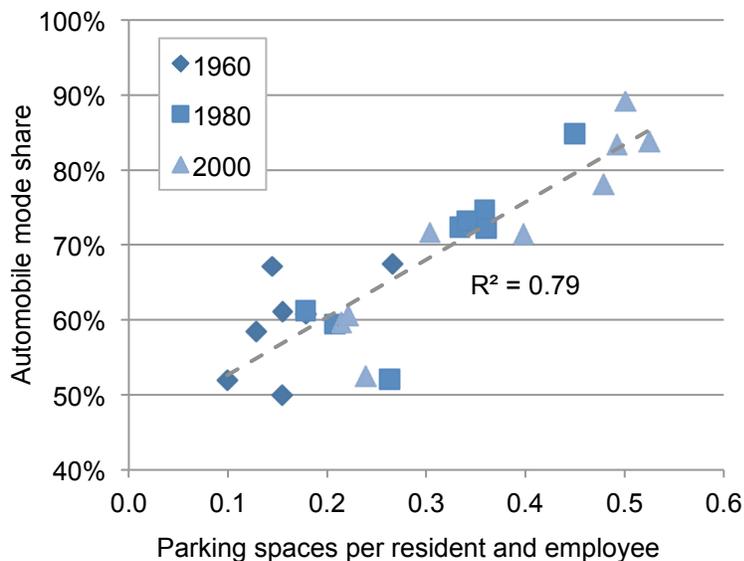

41 The U.S. Census reports place-based journey to work flows by travel mode as early as 1960.  
42 These are reported in printed Journey to Work records from 1960 to 1980 and as part of the  
43 Census Transportation Planning Products (CTPP) from 1990 to the present. They allow us to  
44 calculate the number of residents and employees commuting to or from each city and the  
45 automobile mode share for each year of interest. They also allow us to isolate local commute

trips—those that begin and end within a city. Data on workers and local trips are not available for Lowell in 1960 or for Silver Spring between 1960 and 1980.

By focusing only on the commuting behavior of residents, we also gain a more robust data set that reflects all of cities—including Lowell and Silver Spring—dating back to 1960. These data are available at the census tract level from the National Historical Geographic Information System (32).

### APPLYING THE BRADFORD HILL CRITERIA

Bradford Hill and other researchers note that before the nine criteria can be employed, a clear association between the treatment and the outcome must first be established (22, 23). As shown in Figure 1, we consider the relationship between parking provision (parking spaces per resident and employee) and automobile use (automobile mode share for workers) for each year and observe a clear, consistent association ( $R^2 = 0.79$ ).

**Figure 1.** Parking provision versus automobile use for those who live or work in a city, 1960-2000. (Data not available for Lowell in 1960 or Silver Spring in 1960 and 1980)

#### Strength

Strength of association is the first of nine criteria identified by Hill. It states that a large response in relation to treatment is a compelling indication of causality. As an example, Hill cites the fact that cigarette smokers are nine to ten times more likely to die from lung cancer than non-smokers.

When the treatment is a simple binary—e.g., smokers versus non-smokers—it is helpful to think of strength in terms of relative risk. Courts, for example, have found that a relative risk of 2.0—meaning that the risks are twice as high for a treatment group—indicates an agent is more likely than not to have caused a disease, but more than one study is needed. Some scholars recommend a relative risk of 3.0 (23). Hill is careful to note, however, that one “must not be too ready to dismiss a cause-and-effect hypothesis merely on the grounds that the observed association appears to be slight” (22).

For this study, we consider the association to be strong if the slope of the curve in Figure 1 is large, indicating that changes in parking provision are associated with large changes in

1 automobile use. The slope is 0.77 ( $p$ -value < 0.00), meaning that a change of 0.1 parking spaces  
2 per person corresponds with a difference in automobile mode share of 7.7 percent. If we consider  
3 cities with 0.2 parking spaces per person as our control group and those with 0.5 parking spaces  
4 per person as our treatment group, the expected rates of automobile use are 60 and 83 percent,  
5 respectively—a relative risk of 1.4. Compared to epidemiological risks, this is somewhat low,  
6 but still consequential. In terms of urban automobile use and its related impacts, this is quite  
7 substantial.

## 8 9 **Consistency**

10 Consistency refers to whether an association has been observed repeatedly by different  
11 individuals, in different situations, and at different points in time.

12 As shown in Figure 1, the relationship between parking provision and automobile use has  
13 held up fairly consistently over a 40-year period from 1960 to 2000 for the cities in this study  
14 and, if anything, that relationship has grown stronger. Few other studies look explicitly at the  
15 relationship between parking supply and automobile use, which makes it somewhat challenging  
16 to ensure consistency. Existing studies, however, validate the general idea that parking  
17 availability and automobile use are positively associated.

18 One recent study modeled the relationship between parking availability and automobile  
19 mode share at the census tract level in New York (8), revealing that commuters to Manhattan’s  
20 core are far more likely to travel by private automobile when there are more off-street parking  
21 spaces available per dwelling unit at their home location. An earlier, related study reached  
22 similar conclusions by comparing two New York City neighborhoods (9). Two studies of New  
23 York City also found that parking availability at home is positively associated with automobile  
24 ownership, which serves as a proxy for automobile use (30), and with automobile use directly  
25 (33). A separate study of automobile ownership in New York City found that a 10 percent  
26 increase in parking requirements is associated with a five percent increase in vehicles per square  
27 mile and a four percent increase in vehicles per person (34).

28 Kuzmyak et al. (11) provide data from a 1997 survey of 17 cities around the U.S., which  
29 show that the share of commuters traveling by single occupancy vehicle increases as the number  
30 of spaces per employee increases. Supplemental data from one study of urban centers in New  
31 England (35) shows a similar relationship between parking ratios—the number of parking spaces  
32 per unit area of building space—and automobile mode share (36).

33 International examples also validate this association. In Edinburgh, Scotland, one study  
34 found that automobile use was considerably lower within a limited parking zone than outside the  
35 zone, and that a 1.5-mile (2.5-km) expansion of that zone could reduce automobile use by 21  
36 percent for commute trips (37). Stated preference surveys in Haifa, Israel, show that reductions  
37 in parking availability could make 23 to 45 percent of workers and 16 to 25 percent of non-  
38 workers change modes, depending on how long parking search times increased (7).

39 Finally, numerous studies show that parking price—which is different from availability,  
40 but often related—also affects automobile use (4–6, 11, 38–40).

## 41 42 **Specificity**

43 Specificity refers primarily to instances in which the treatment effect is the only clear  
44 explanation for an outcome. As Woodside and Davis (23) explain, “The crux of the specificity  
45 consideration is that causality is likely if a very specific population at a specific site develops a  
46 disease with no other likely explanation.”

1 One study, in particular, allows us to consider the issue of parking supply and automobile  
2 use through this lens. Weinberger et al. (9) studied two specific neighborhoods in New York—  
3 Jackson Heights in Queens and Park Slope in Brooklyn—to understand how parking availability  
4 at home influences individuals' decision to drive to work. The authors summarize their findings  
5 as follows:

6  
7 *Indicators such as income, car ownership, density, government employment, and the*  
8 *difference between drive and transit times to the central business district (CBD) predict a*  
9 *higher share of auto commuting by Park Slope residents. Yet Jackson Heights residents*  
10 *are 45% more likely to drive to work in the Manhattan CBD and 28% more likely to*  
11 *commute by car in general.*

12  
13 They attribute this unlikely outcome to the fact the Jackson Heights has considerably  
14 more off-street parking. Specifically, residents are more than 2.5 times more likely to have  
15 access to off-street parking and more than six times as likely to have an on-site, private parking  
16 space. The authors conclude that guaranteed parking at home is the only clear factor explaining  
17 the relatively high rates of automobile use in that neighborhood.

### 18 19 **Temporality**

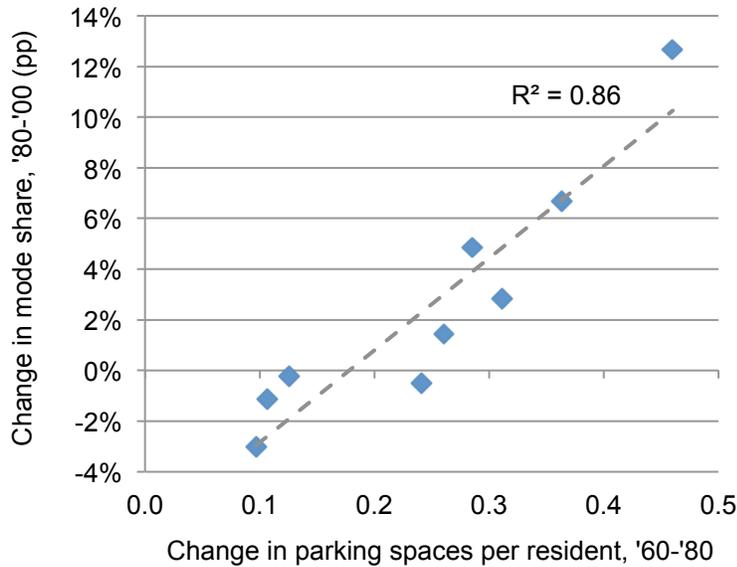

20 Temporality refers to the sequence of events governing an association and requires that a  
21 treatment must come before the outcome. This criterion is particularly difficult to test, in our  
22 case, given the broad time-scale of our analysis and the complex interactions among factors. For  
23 example, while parking provision may contribute to rising levels of automobile use, it is also  
24 likely that, conversely, trends in automobile use affect parking policy and, thus, parking  
25 provision.

26 To test this, we assume that if one factor precedes another, we should be able to predict  
27 the latter by looking at prior changes in the former. As an analogy, this implies that an  
28 individual's smoking habit can predict whether they will later develop lung cancer, but instances  
29 of lung cancer cannot necessarily predict whether somebody will take up smoking.

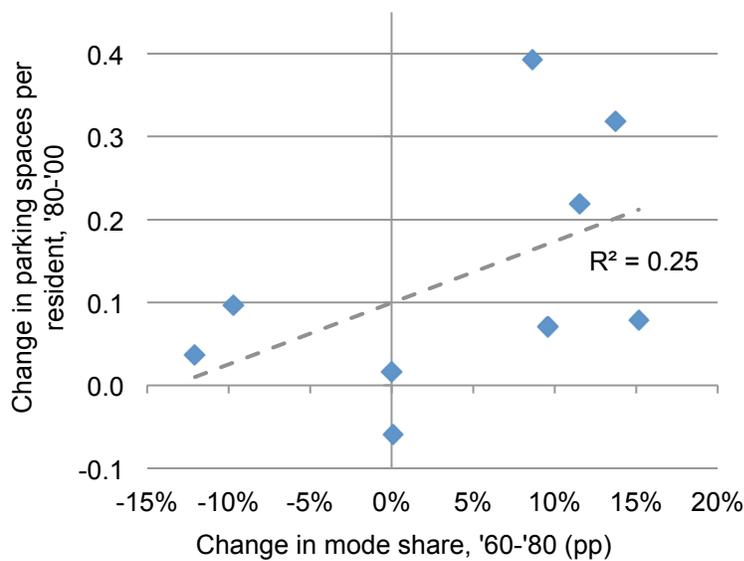

30 As shown in Figure 2, increases in the number parking spaces per resident between 1960  
31 and 1980 are directly correlated with increases in resident automobile use the following two  
32 decades ( $R^2 = 0.86$ ). However, changes in automobile use before 1980 are a much weaker  
33 predictor of parking increases after 1980 ( $R^2 = 0.25$ ), as shown in Figure 3.

34 This is compelling evidence that even though the relationship between parking and  
35 driving is complex, parking provision appears to be the primary leading factor. Using the same  
36 analogy as above, this is like saying that even though somebody might begin smoking after  
37 developing lung cancer (possibly because their risk of developing cancer no longer exists),  
38 smoking is still the primary leading factor of lung cancer.

39

1  
2 **Figure 2.** Change in parking provision (1960-1980) versus change in automobile use by  
3 residents (1980-2000)  
4

5  
6 **Figure 3.** Change in automobile use by residents (1960-1980) versus change in parking  
7 provision (1980-2000)  
8

9 **Biological gradient**

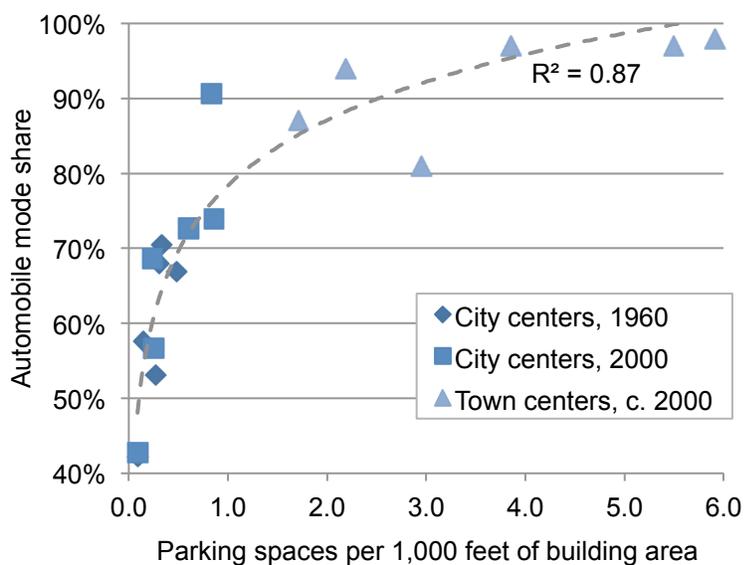

10 The biological gradient criterion states that a clear dose-response curve is strong evidence of  
11 causality. Hill points again to the case of lung cancer in smokers, which follows a linear  
12 relationship. A lower death rate among the heaviest smokers would be problematic, he suggests,  
13 but not necessarily evidence against causality.

14 For this study, we refer again to Figure 1, which shows there is a clear, linear relationship  
15 between parking provision and automobile use. For those cities with the largest supplies of  
16 parking, rates of automobile use are considerably higher and the relationship is exceptionally

1 strong in this higher range. In the most extreme cases, where there more than 0.4 spaces per  
 2 person, more than 75 percent of commuters travel by automobile.

3 Dose-response curves in conventional epidemiological studies often follow an S-shape  
 4 curve or some other non-linear form (23). Although our data show a linear relationship, we  
 5 expect some curvature outside the range of our data. Because automobile mode share cannot  
 6 exceed 100 percent, we expect this curve to level off as parking increases and mode share  
 7 approaches its maximum.

8 Data from two previous studies looking at town and city centers, reproduced in Figure 4,  
 9 validate this concept (35, 36). As the number of parking spaces per 1,000 square feet (92.9  
 10 square meters) of building area increases, the automobile mode share also increases but levels off  
 11 as it approaches 100 percent. The regression line shown in Figure 4 represents the relationship  
 12 between automobile use and the natural log of parking provision ( $R^2 = 0.87$ ).  
 13

14  
 15 **Figure 4.** Parking provision versus automobile use for town and city centers (35, 36)  
 16

17 **Plausibility and coherence**

18 Hill identifies plausibility and coherence as two separate criteria. In epidemiological studies,  
 19 plausibility suggests that there is a reasonable biological explanation for a particular treatment to  
 20 cause a particular outcome—e.g., a mechanism by which smoking could cause lung cancer. In  
 21 contrast, coherence suggests that a theory of causality should not conflict with general  
 22 knowledge about the nature of a relationship. As Woodside and Davis (23) explain, “The  
 23 difference between coherence and plausibility would seem, in part, to be one of semantics”—one  
 24 suggests that evidence supports the theory and the other suggesting that evidence does not  
 25 conflict. Therefore, we consider the plausibility and coherence criteria together.

26 In fact, general knowledge outside of academic research and separate from the practice of  
 27 transportation demand management might suggest that automobile use is fairly inelastic and that  
 28 parking demand is predetermined. This perspective stems partly from the fact that parking is  
 29 often plentiful and usually not paid for by users (41), which leads many people to expect free,  
 30 convenient parking at every destination (42). The most common parking policies—minimum  
 31 parking requirements—and the information on which they are often based also assume that  
 32 almost all visitors will arrive by automobile (43, 44) and that demand is fairly inelastic. While

1 the evidence base for this approach is not particularly strong, these assumptions are widely held  
2 (*1*).

3 The mechanisms through which parking availability influences automobile use are fairly  
4 well understood. The influence of parking rests in the fact that parking price and availability  
5 affect the costs of driving, relative to other modes, in terms of time or money. A majority of the  
6 research in this area focuses on the effects of parking price, rather than its availability (*4–6, 11,*  
7 *38–40*). Generally, when parking costs are paid directly by the user, she or he can make more  
8 informed mode choice and trip-making decisions. Less research has considered the influence of  
9 parking availability, but the existing studies point to a similar effect (*7–9, 11, 33, 37, 38*). As  
10 parking becomes less available and search times increase, people are less willing to give up their  
11 parking space or search for a new space and, instead, choose alternative modes or change their  
12 trip-making behavior in other ways—for example, by parking once and walking to multiple  
13 destinations, instead of making multiple trips by automobile.

14 The influences of parking price, in particular, are widely recognized in tools for  
15 estimating travel demand and mode share, even if they are seldom reflected in parking policies.  
16 The Oregon Sustainable Transportation Initiative’s Greenhouse Gas Reduction Toolkit and the  
17 Oregon Department of Transportation’s Mosaic planning tool assume that priced parking can  
18 reduce vehicle miles traveled by 0.8 to 1.8 percent over a period of 20 years (*45*). The U.S.  
19 Environmental Protection Agency’s COMMUTER model accounts for parking costs in  
20 estimating automobile versus transit mode shares (*46*). The Florida Department of  
21 Transportation’s Trip Reduction Impacts of Mobility Management Strategies (TRIMMS), which  
22 is used to estimate travel demand reductions for different policies levers, includes parking price  
23 elasticities (*47*). Its Worksite Trip Reduction Model (WTRM) accounts for priced parking and  
24 other parking management strategies in estimating the impacts of employer-based trip reduction  
25 programs (*48*).

## 26 27 **Experiment**

28 A randomized controlled experiment is typically the preferred method for establishing causality.  
29 However, in the context of urban policy, perhaps even more than in epidemiology, controlled  
30 experiments are extremely difficult to conduct.

31 Nonetheless, some known quasi-experiments exist. As Hill suggests, these are instances  
32 of preventative measures—i.e., restrictions on parking availability—that lead to apparent  
33 decreases in automobile use. Many of these quasi-experiments occur when employers implement  
34 parking restrictions, either because of limited availability or as part of transportation demand  
35 management programs.

36 In Hartford, for example, a majority of the city’s largest employers offer free parking to  
37 employees. Rates of automobile use at those companies are between 83 and 95 percent. One  
38 major insurance company, however, now charges employees a monthly fee in order to manage  
39 parking demand. At that location, only 71 percent of employees drive alone to work (*12*). Other  
40 employers and parking districts in different locations have experienced similar outcomes (*11*).  
41 The Hartford example, however, is particularly important to consider since it is one of the more  
42 automobile-oriented cities in our study. We can reason that similar measures, if replicated across  
43 the city, could have a substantial effect on commuter automobile use.

## 1 **Analogy**

2 Hill says little about the use of analogy in judging whether a relationship is causal, except that:  
3 “With the effects of thalidomide and rubella before us we would surely be ready to accept  
4 slighter but similar evidence with another drug or another viral disease in pregnancy” (22). Other  
5 researchers interpret this to mean that if one treatment has been shown to produce a particular  
6 outcome, less evidence is needed to show that similar treatments could produce a similar effect  
7 (23, 24). However, the use of analogy as evidence has also garnered criticism (24).

8 In the fields of urban and transportation planning, analogy is a particularly challenging  
9 criterion to satisfy. Many land use and transportation factors are known to affect travel behavior  
10 (49), so the effects of parking should not take any great leap of the imagination. However, many  
11 of these factors are also interrelated, rather than analogous. Taking that into account, as well as  
12 criticisms of the criterion in general, we consider it only partially met, but not particularly  
13 applicable.

## 14 **IMPLICATIONS FOR PARKING POLICY**

15 According to Phillips and Goodman (25), Hill looked at the decision-making process through an  
16 economic lens and believed in weighing the potential costs and benefits of a policy decision  
17 before acting on any piece of evidence, however strong or weak that evidence may be. In our  
18 case, the costs of providing abundant parking without charging its users directly are too high to  
19 be overlooked, particularly in urban areas (3). These include costs with associated land  
20 acquisition, construction, maintenance and operations, plus added impacts like traffic congestion  
21 (50), environmental degradation (51), lost tax revenues (52) and other externalities (53). In  
22 contrast, as noted by Weinberger (8), there is little evidence that parking restrictions hurt urban  
23 areas economically and some evidence to suggest that parking capacity and economic decline are  
24 actually associated. Voith (54, 55) finds that abundant parking in urban areas is more likely to be  
25 a sign of economic distress than a competitive advantage, arguing that cities generally should not  
26 encourage adding parking capacity in their central business districts.

27 Applying the Bradford Hill criteria to understand the causal nature between parking  
28 provision and automobile use in American cities poses some challenges. For example, not every  
29 criterion can be thoroughly evaluated using the available data. This is due in large part to a  
30 general lack of studies aimed at answering this particular research question. This suggests that  
31 more research might be necessary to satisfy the most rigorous scientific standards for inferring  
32 causality. This challenge is made even more complicated because the relationship between  
33 parking and driving, as with many factors in urban planning, is complex and because reliable  
34 data about parking is so rare.

35 In light of all the available evidence, however, there is a strong case for restricting and  
36 reducing parking capacity in urban areas, particularly as a means of curbing high levels of  
37 automobile use. The Bradford Hill criteria provide a framework to infer with a reasonable  
38 amount of certainty that parking increases have contributed substantially to rising automobile use  
39 in cities.

## 40 **CONCLUSIONS**

41 For this study, we combine original data from nine U.S. cities over a period of 40 years  
42 with knowledge gained from prior research in order to apply the Bradford Hill causality criteria  
43 and better understand the influence of parking provision on automobile use. At the city scale, we  
44 find that an increase in parking provision from 0.1 to 0.5 parking spaces per resident and  
45

1 employee is associated with an increase in commuter automobile mode share of roughly 30  
2 percentage points. We also demonstrate that a majority of the Bradford Hill criteria can be  
3 satisfied using the available data. While there is some lack of relevant data and research, none of  
4 available evidence conflicts with the Bradford Hill criteria. Based on this knowledge, we infer  
5 that parking provision in cities is a likely cause of increased driving among residents and  
6 employees in those places. Given the costs associated with parking and its apparent effects on  
7 automobile use, our findings suggest that policies to restrict and reduce parking capacity in cities  
8 are warranted.
